Kapteyn Astronomical Institute
University of Groningen

2026

Learning objectives

By the end of this lecture, you will be able to:

- Classify atmospheres as primary, secondary or tertiary
- Derive the scale height from hydrostatic equilibrium and apply it across the solar system
- Explain the greenhouse effect and the escape mechanisms that decide which atmospheres survive

Recap: Lecture 4

Credit: NASA/ISS Expedition 21 crew, public domain

- Metal-silicate separation in magma oceans formed cores within ~30–60 Myr
- A dynamo needs a conducting fluid, convection and $R_m \gtrsim 10\text{--}100$
- Mars lost its dynamo between ~4.1 and 3.7 Ga, then its atmosphere

Today: The thin gaseous envelope that controls a planet's surface conditions.

A photograph of the surface of Venus taken by the Venera 13 lander in 1982. The image shows a dark, granular surface with some larger, lighter-colored rocks. A portion of the lander's structure, including a series of triangular sensors or antennas, is visible in the lower-left corner. The overall color palette is dominated by dark browns and greys, with some lighter tan and yellowish hues on the rocks and the lander's components.

1. Atmospheric composition

The surface of Venus under its 92-bar atmosphere, Venera 13 (1982). Credit: USSR/NASA NSSDC, public domain

Primary atmospheres

Captured directly from the protoplanetary disk.

- Dominated by H_2 and He (solar composition)
- **Gas giants** keep massive H_2/He envelopes; **ice giants** only 10–20% of their mass
- Terrestrial planets are too small to retain primordial H_2/He

Growth of a giant planet by core accretion: runaway gas accretion builds the H₂/He envelope once it outweighs the core. Reproduced from Helled et al. (2014), Fig. 1; simulation from Lissauer et al. (2009).

A primary atmosphere needs a core of $\geq 5\text{--}10 M_{\oplus}$ before the disk disperses in $\sim 3\text{--}10$ Myr.

Secondary atmospheres

Produced by outgassing from the interior.

- Magma ocean degassing and volcanism release dissolved volatiles
- Speciation follows the mantle **oxygen fugacity**: oxidising CO_2 , H_2O , N_2 ; reducing H_2 , CO , N_2
- **Venus**: 96.5% CO_2 at 92 bar; **Mars**: 95% CO_2 at 6 mbar; **Titan**: N_2 at 1.5 bar

Speciation of an outgassed atmosphere against melt oxygen fugacity: CO , H_2 and CH_4 when reducing, CO_2 and H_2O when oxidising. Course figure; model of Nicholls et al. (2024).

Earth's atmospheric oxygen through time: anoxic for ~2 Gyr, rising at the Great Oxidation Event near 2.4 Ga, modern levels in the Phanerozoic. Reproduced from Lyons et al. (2014).

Earth's atmosphere is **tertiary**: photosynthesis added the 21% O_2 , which is biogenic and needs active life to persist.

Comparative atmospheric properties

	Venus	Earth	Mars	Jupiter	Titan
P_{surf} (bar)	92	1.0	0.006	n/a	1.5
T_{surf} (K)	737	288	215	n/a	94
Dominant gas	CO ₂	N ₂	CO ₂	H ₂	N ₂
Secondary gas	N ₂	O ₂	N ₂	He	CH ₄
μ	43.4	28.97	43.3	2.2	27.4
Type	2*	3*	2*	1*	2*

Surface pressures span four orders of magnitude, temperatures run from 94 to 737 K.

Atmospheric composition of five solar-system bodies

Atmospheric composition by volume for five solar-system bodies: three origins yield five distinct outcomes. Course figure.

The surface of Venus seen by *Venera 13* on 1 March 1982. Credit: USSR/NASA NSSDC, public domain.

The lander survived 127 minutes at 92 bar and 737 K; the CO₂ atmosphere and clouds filter sunlight to a dim orange glow.

2. Hydrostatic equilibrium

The thin atmosphere of Mars above its limb, Viking 1 (1976). Credit: NASA/JPL

Hydrostatic equilibrium

Credit: Course figure

The **pressure gradient** across a thin slab of area A and thickness dz balances its weight:

$$P(z)A - P(z + dz)A = \rho g A dz$$

$$\frac{dP}{dz} = -\rho g$$

Each layer supports the weight of all gas above it.

The ideal gas law and barometric formula

The ideal gas law $P = \rho k_B T / (\mu m_u)$ in $\frac{dP}{dz} = -\rho g$ gives

$$\frac{dP}{dz} = -\frac{\mu m_u g}{k_B T} P = -\frac{P}{H}$$

For an **isothermal** atmosphere (constant T):

$$P(z) = P_0 \exp\left(-\frac{z}{H}\right)$$

with $H = k_B T / (\mu m_u g)$; the pressure drops by a factor of $e \approx 2.718$ each scale height.

Ideal gas law in atmospheric form, $\rho = P\mu m_u / (k_B T)$: density scales with pressure at fixed T , heavier or colder gas is denser. Course figure.

(a) Linear scale

(b) Logarithmic scale

The barometric formula $P/P_0 = e^{-z/H}$: a factor e per scale height, 99% of the column mass below $4.6 H$, a straight line on a logarithmic axis. Course figure.

3. Blackboard derivation: scale height

Goal and strategy

Goal: derive $H = k_B T / (\mu m_u g)$ from hydrostatic equilibrium and the ideal gas law.

- Balance the forces on a thin slab
- Replace ρ by P with the ideal gas law
- Read off the length scale, integrate, compute

One length, H , sets how fast pressure falls with height.

Deriving the scale height

Start from:

$$\frac{dP}{dz} = -\rho g \quad \text{and} \quad P = \frac{\rho k_B T}{\mu m_u}$$

Express ρ in terms of P :

$$\rho = \frac{P \mu m_u}{k_B T}$$

Substitute:

$$\frac{dP}{dz} = -\frac{\mu m_u g}{k_B T} P \equiv -\frac{P}{H}$$

The atmospheric scale height

$$H = \frac{k_B T}{\mu m_u g}$$

- **Higher T** → larger H : hotter gas extends further
- **Heavier molecules** (larger μ) → smaller H : harder to loft
- **Stronger gravity g** → smaller H : more compressed

H balances thermal energy against gravitational binding; integrated over the column, the surface pressure is the column weight, $P_0 = m_{\text{col}} g$.

Scale heights across the solar system

Body	T (K)	μ	g (m s^{-2})	H (km)
Venus	737	43.4	8.87	15.9
Earth	288	28.97	9.81	8.4
Mars	215	43.3	3.72	11.1
Jupiter	165	2.2	24.8	25
Titan	94	27.4	1.35	21

- Jupiter: large H despite strong gravity, because H_2 is very light ($\mu = 2.2$)
- Titan: large H despite low T , thanks to very weak gravity ($g = 1.35 \text{ m s}^{-2}$)
- Venus: hot, but heavy molecules and decent gravity yield a moderate H

Atmospheric scale heights: $H = k_B T / (\mu m_u g)$

Scale heights recomputed from T , μ and g : light gas (Jupiter) and weak gravity (Titan) give the largest H , Earth the smallest. Course figure.

4. Vertical structure

Titan's stratified haze layers, Cassini. Credit: NASA/JPL/Space Science Institute (PIA06160)

Earth's atmospheric layers, defined by the sign of $\frac{dT}{dz}$. Course figure; US Standard Atmosphere 1976.

Troposphere (0–12 km): T falls, convective; **stratosphere** (12–50 km): T rises by UV ozone heating; **mesosphere** (50–85 km): T falls to the ~190 K mesopause; **thermosphere** (>85 km): EUV heating, $T > 1000$ K.

The adiabatic lapse rate

In the troposphere, convection sets the temperature gradient:

$$\Gamma_d = -\frac{dT}{dz} = \frac{g}{c_p}$$

- **Dry adiabatic lapse rate** for Earth:
 $\Gamma_d = 9.81/1004 = 0.0098 \text{ K m}^{-1} \approx 9.8 \text{ K km}^{-1}$; observed $\sim 6.5 \text{ K km}^{-1}$ because of latent heat
- Rising air expands, does work on its surroundings, and cools
- **Tropopause height:** $\sim 8 \text{ km}$ (poles) to $\sim 17 \text{ km}$ (equator)

Dry and moist adiabats against the US Standard Atmosphere 1976: latent heat makes the moist adiabat shallower, and real convection sits between both limits. Course figure.

Titan's temperature profile from the Huygens HASI descent: the 94 K surface, the 0.1 bar tropopause and the stratosphere measured in situ. Fulchignoni et al. (2005).

Detached haze layers in Titan's upper atmosphere, Cassini ISS: photochemical haze up to 500 km altitude absorbs solar UV and heats the stratosphere. Credit: NASA/JPL/Space Science Institute, public domain.

Venus temperature profile from Pioneer Venus/VIRA and Venus Express: without ozone, T falls monotonically from 737 K at the surface to the mesopause near 100 km. Course figure.

Measured temperature-pressure profiles of seven solar-system atmospheres: thick atmospheres turn from convective to radiative near 0.1 bar, a universal tropopause. Digitized from Robinson & Catling (2014), Fig. 1.

5. Radiative transfer basics

Three interactions: radiation and matter

- **Absorption:** photon energy becomes molecular energy; key absorbers CO_2 , H_2O , CH_4 , O_3
- **Emission:** warm gas radiates at the same wavelengths (Kirchhoff's law); only $\tau \lesssim 1$ reaches space
- **Scattering:** redirection without absorption; Rayleigh ($\propto \lambda^{-4}$) and Mie

Rayleigh scattering and the colour of the sky: short paths at noon keep the blue scattered light, long slant paths at sunset transmit only red; the cross-section scales as λ^{-4} . Course figure.

Blackbody spectra of the Sun ($\sim 5800 \text{ K}$, peak $\sim 0.5 \mu\text{m}$) and a planet ($\sim 300 \text{ K}$, peak $\sim 10 \mu\text{m}$).

Credit: Wikimedia, public domain.

This **wavelength separation** is the basis of the greenhouse effect: transparent in the visible, opaque in the infrared.

Optical depth and the Beer-Lambert law

Optical depth τ measures the cumulative absorption along a path:

$$\tau = \int_0^s \kappa \rho \, ds'$$

Beam intensity decays following the **Beer-Lambert law**:

$$I = I_0 e^{-\tau}$$

- **Optically thin** ($\tau \ll 1$): radiation passes freely through the gas
- **Optically thick** ($\tau \gg 1$): photons are absorbed and re-emitted many times
- **Photosphere** ($\tau \approx 1$): thermal radiation escapes directly to space

(a) Beer-Lambert attenuation

(b) The atmospheric photosphere

The atmospheric photosphere: thermal radiation escapes to space from the $\tau \approx 1$ level, which sets the effective temperature. Course figure.

Earth's atmospheric absorption spectrum from UV to IR: greenhouse gases absorb the outgoing infrared while visible sunlight and the 8–13 μm window pass. Credit: Wikimedia Commons, public domain.

Break

6. Energy balance & greenhouse effect

Radiative-convective equilibrium (schematic): the radiative profile is superadiabatic near the surface, convection holds the troposphere on the dry adiabat. Course figure.

Troposphere convective, **stratosphere** in radiative equilibrium, **tropopause** where the radiative gradient drops below the adiabat.

Planetary energy balance

Absorbed stellar power equals emitted thermal radiation:

$$(1 - A) \frac{S}{4} = \sigma T_{\text{eq}}^4 \quad \text{where} \quad S = \frac{L_{\star}}{4\pi d^2}$$

- A: Bond albedo; S: stellar flux ($S_0 = 1361 \text{ W m}^{-2}$ at Earth); T_{eq} is also written T_{eff}
- Factor 1/4: intercepting cross-section πR_p^2 over the emitting sphere $4\pi R_p^2$

$$T_{\text{eq}} = \left[\frac{(1 - A) L_{\star}}{16\pi\sigma d^2} \right]^{1/4} = \left[\frac{(1 - A) S}{4\sigma} \right]^{1/4}$$

Earth's globally averaged energy budget in W m^{-2} : back-radiation of 333 W m^{-2} supplies more energy to the surface than the sunlight absorbed at the surface (160 W m^{-2}). After Trenberth et al. (2009).

Effective vs. surface temperature

Body	A	d (AU)	T_{eq} (K)	T_{surf} (K)	ΔT (K)
Venus	0.77	0.72	227	737	+510
Earth	0.30	1.00	255	288	+33
Mars	0.25	1.52	210	215	+5
Jupiter	0.34	5.20	110	165*	+55

*Jupiter 1-bar level; excess partly from internal heat (Lecture 3).

$\Delta T = T_{\text{surf}} - T_{\text{eq}}$ is the **greenhouse effect**: 510 K on Venus, 33 K on Earth, ~5 K on Mars (6 mbar, no water-vapour amplifier).

Surface temperature and pressure of Venus, Earth and Mars: similar bulk compositions span a factor 10^4 in pressure and 500 K in temperature through greenhouse warming. Course figure; data from NASA.

The one-layer greenhouse model: sunlight in, infrared absorbed and re-emitted half up, half down. Course figure.

Sunlight ($\sim 0.5 \mu\text{m}$) reaches the surface, the surface emits thermal IR ($\sim 10\text{--}15 \mu\text{m}$), greenhouse gases absorb it and re-emit half downward, and that extra energy makes $T_{\text{surf}} > T_{\text{eq}}$.

One-layer greenhouse model

A single layer with infrared emissivity ε , transparent to visible sunlight:

Flux balance:

$$\text{Atmosphere: } \varepsilon \sigma T_s^4 = 2\varepsilon \sigma T_a^4$$

$$\text{Surface: } (1 - A) \frac{S}{4} + \varepsilon \sigma T_a^4 = \sigma T_s^4$$

$$\text{TOA: } (1 - A) \frac{S}{4} = \sigma T_{\text{eq}}^4$$

- $\varepsilon = 0$ (transparent): $T_s = T_{\text{eq}}$
- $\varepsilon = 1$ (opaque): $T_s = 2^{1/4} T_{\text{eq}} \approx 1.19 T_{\text{eq}}$ (Earth: $\approx 303 \text{ K}$)

Surface temperature:

$$T_s = T_{\text{eq}} \left(\frac{2}{2 - \varepsilon} \right)^{1/4}$$

The image features two spheres side-by-side against a dark blue background. The sphere on the left is Mars, showing detailed surface features like polar ice caps and various colored regions. The sphere on the right is a lighter, more uniform tan color, representing Mars during a global dust storm. The text '7. Atmospheric escape' is centered between the two spheres.

7. Atmospheric escape

Thermal (Jeans) escape

The high-velocity tail of the Maxwell-Boltzmann distribution can exceed the escape speed. The **Jeans escape parameter** at the exobase compares gravitational to thermal energy:

$$\lambda_J = \frac{GM_p m}{k_B T_{\text{exo}} r_{\text{exo}}} = \frac{v_{\text{esc}}^2}{v_{\text{th}}^2}, \quad v_{\text{th}} = \sqrt{2k_B T_{\text{exo}} / m}$$

- $\lambda_J \gg 1$: escape is slow (exponentially suppressed) because very few molecules exceed v_{esc}
- $\lambda_J \lesssim 2-3$: thermal escape drives rapid atmospheric loss
- Escape flux $\Phi_J \propto (1 + \lambda_J) e^{-\lambda_J}$: exponential in λ_J

The main atmospheric escape processes: thermal, photochemical and ion channels act on all planets, and the magnetic field selects which dominate. Gronoff et al. (2020).

Jeans parameter for Earth and Mars

Exobase temperatures: 1000 K (Earth), 270 K (Mars).

Species	m (u)	λ_j (Earth)	λ_j (Mars)
H	1	7.0	5.3
H ₂	2	14	11
He	4	28	21
N ₂	28	200	150
CO ₂	44	310	230

$\lambda_j \propto m$: atomic H escapes steadily from both planets, while N₂ and CO₂ stay gravitationally bound.

The exobase: the altitude where the mean free path ℓ equals the scale height H , collisional fluid below and ballistic flight above. Course figure.

Maxwell-Boltzmann speed distributions for atomic H at the Earth and Mars exobases: the escaping fraction is the tail beyond v_{esc} , scaling as $e^{-\lambda}$. Course figure.

Hydrodynamic escape

Intense stellar EUV heating drives bulk outflow as an **atmospheric wind**:

- Strongest in the first few hundred Myr, when stellar EUV is 10–100× higher
- Strips H_2 envelopes from planets up to several $M_{\oplus}$; outflowing H drags heavier gases along
- Carves the exoplanet radius valley at $\sim 1.5\text{--}2 R_{\oplus}$

Source: Hunten et al. (1987); Owen (2019)

The radius valley in the California-Kepler Survey: a deficit near $1.8 R_{\oplus}$ separates stripped rocky cores from envelope-retaining sub-Neptunes. After Fulton et al. (2017).

Population synthesis after 10 Gyr of EUV-driven escape: an empty evaporation desert and a valley near 1.5 to 2 $R_{\oplus}$. After Owen & Wu (2013), Lopez & Fortney (2013) and Owen (2019).

Energy-limited escape rate

Stellar EUV absorbed in the upper atmosphere drives hydrodynamic mass loss:

$$\dot{M}_{\text{EL}} = \eta \frac{\pi F_{\text{EUV}} R_p^3}{G M_p}$$

- Efficiency $\eta \approx 0.1\text{--}0.2$ converts incident EUV flux into expansion work
- Scales as R_p^3 : extended, low-density atmospheres lose mass fastest
- Scales inversely with M_p : low gravity enables stronger bulk outflow

Source: Watson et al. (1981); Owen (2019)

Hydrodynamic outflow from a hot Jupiter under stellar EUV heating: the gas accelerates outward into a night-side wake with Kelvin-Helmholtz instabilities. Reproduced from Owen (2019), Fig. 2; simulation from Tripathi et al. (2015).

Non-thermal escape mechanisms

- **Sputtering** and **ion pickup**: solar wind ions eject neutrals, and photoions are swept away by the interplanetary field
- **Photochemical**: photodissociation yields suprathermal atoms above v_{esc}
- **Impact erosion**: giant impacts shock and eject atmospheric columns

MAVEN at Mars: photochemical loss of oxygen dominates modern escape over sputtering and ion pickup.

Present-day oxygen loss from Mars

Present-day oxygen loss from Mars by channel: photochemical escape dominates, and with hydrogen escape the total reaches the $2\text{--}3 \text{ kg s}^{-1}$ MAVEN measures. After Jakosky et al. (2018).

The ion plume of Mars from MAVEN: energetic ions (red) leave in a plume, the bulk (green) along the tail, with no global field to keep the solar wind out. Credit: NASA Scientific Visualization Studio (SVS 4370), public domain.

A close-up, curved view of Jupiter's atmosphere, showing the Great Red Spot as a large, reddish-orange oval storm system. The surrounding atmosphere is a mix of light and dark brown bands, with swirling patterns indicating high-speed winds. The text "8. Atmospheric retention" is centered over the Great Red Spot.

8. Atmospheric retention

Escape velocity against temperature, with the retention lines for each gas.
Credit: Wikimedia, CC BY-SA 4.0.

Long-term retention needs $v_{\text{esc}} \gtrsim 6 v_{\text{th}}$: gas giants keep every species, Earth and Venus lose the light gases H and He, Mars is marginal, cold Titan keeps N_2 , the Moon and Mercury keep nothing.

The thin atmosphere of Mars above its limb, Viking 1 (1976). Credit: NASA/JPL.

After the dynamo died (~4.1 Ga) the solar wind eroded a dense early atmosphere down to today's 6 mbar: no stable liquid water.

9. Recent advances & outlook

JWST/MIRI 15 μm thermal emission matches a 503 K bare rock, ruling out a thick atmosphere on TRAPPIST-1 b. Greene et al. (2023).

X-ray luminosity evolution of Sun-like stars and M dwarfs: low-mass stars stay saturated for over 1 Gyr and strip close-in rocky planets for longer. Reproduced from Johnstone et al. (2021), Fig. 11.

Summary

1. **Atmosphere types:** primary (captured), secondary (outgassed), tertiary (biogenic); four orders of magnitude in surface pressure
2. **Hydrostatic balance** and the **scale height** $H = k_B T / (\mu m_u g)$ give $P = P_0 e^{-z/H}$; convection sets $\Gamma_d = g/c_p$ below the 0.1 bar tropopause
3. **Greenhouse warming** from $\tau \gtrsim 1$ raises T_s above T_{eq} ; **thermal escape** is negligible when $v_{esc} \gtrsim 6v_{th}$; hydrodynamic and non-thermal loss follow other rules
